Overview

• Insertion Sort
  • Pseudocode
  • Loop Invariants

• Analyzing Algorithms
  • Summations
  • Best, Worst
    Expected Cases
  • Order of Growth

• Designing Algorithms
  • Divide and Conquer
  • Mergesort
  • Recursion
Insertion Sort
Pseudocode is similar to actual programming language code (C, Fortran, Pascal, Java, Python, etc) except that it tries to present an algorithm in the most clear and concise way.
Pseudocode usually ignores software engineering concerns to present the algorithms concisely.

Pseudocode can also use English if that is the easiest way to present a concept.
Pseudocode

You should read up about the book’s conventions on pseudocode for more information.
Insertion Sort

Insertion sort solves the *sorting problem*:

**Input:** A sequence of $n$ numbers $<a_1, a_2, ..., a_n>$

**Output:** A permutation (reordering) $<a'_1, a'_2, ..., a'_n>$ of the input sequence such that $a'_1 \leq a'_2 \leq ... \leq a'_n$. 
The insertion sort algorithm presented sorts the numbers *in place*, they are rearranged within the array instead of inserted into a new array. At most a constant number of values are stored outside that array at any time.
Insertion Sort

Start with an initial unordered array.

5 2 4 6 1 3
Insertion Sort

Pick a key (the element in black).
Insertion Sort

The section of the array in grey is already sorted. We can start with a key in the 2nd position because an array of size 1 is always sorted.
Insertion Sort

Insertion sort proceeds by inserting the key into the sorted array (hence the name).
Insertion Sort

2 5 4 6 1 3

Now we have a longer sorted array, so we can pick a new key (the element in black).
We insert the key (in black) into the sorted array (in grey).
Insertion Sort

Our sorted portion of the array increases, so we select the next element as the key.
## Insertion Sort

We insert the new key into the sorted array. It’s already in the correct position.

| 2 | 4 | 5 | 6 | 1 | 3 |
Insertion Sort

We select the next element as the key.
Insertion Sort

We insert it in the beginning of the sorted array and move everything after it to the right.
The last element of the array is our new key, and everything before it is sorted.
Insertion Sort

Insert the last key into the array and shift everything after it to the right.
We now have a sorted array.
Insertion Sort Pseudocode

INSERTION-SORT(A)
1.   for j = 2 to length[A]
2.       do key = A[j]
3.       //insert A[j] into the sorted sequence A[1..j - 1]
4.       i = j - 1
5.       while i > 0 and A[i] > key
7.            i = i - 1
8.       A[i + 1] = key

Some important things to note:
• This pseudocode is slightly different from the book due to character limitations.
• Arrays indices in C++ go from 0 to length -1, the pseudocode in the book have array indices go from 1 to length.
Loop Invariants

INSERTION-SORT(A)
1. for j = 2 to length[A]
2.   do key = A[j]
3.   //insert A[j] into the sorted sequence A[1..j - 1]
4.   i = j - 1
5.   while i > 0 and A[i] > key
7.     i = i - 1
8.   A[i + 1] = key

The index $j$ indicates the “current card” being inserted into each hand.

At the beginning of the outer for loop (starting on line 1), the subarray A[1 ... j - 1] are the “sorted hand,” while A[j+1 ... length] are the pile of unsorted cards.
Loop Invariants

At the beginning of the outer for loop (starting on line 1), the subarray 
A[1 ... j - 1] are the “sorted hand,” while A[j+1 ... length] are the pile of 
unsorted cards.

We can state these properties of A[1 ... j - 1] formally as a loop invariant:

At the start of each iteration of the for loop of lines 1-8, the 
subarray A[1 ... j - 1] consists of the elements originally in A[1 .. j - 1] 
but in sorted order.
Loop Invariants

Loop invariants can be used to help understand why an algorithm is correct, and also help us reason about it’s speed.
Loop Invariants

Insertion sort loop invariant:

At the start of each iteration of the for loop of lines 1-8, the subarray A[1 ... j - 1] consists of the elements originally in A[1 .. j - 1] but in sorted order.

(This is similar to mathematical induction.)

Initialization: The loop invariant is true on the first iteration of the loop.

Maintenance: If it is true before an iteration of the loop, it remains true before the next iteration.

Termination: When the loop terminates, the invariant gives us a useful property that helps show that the algorithm is correct.
Insertion Sort Loop Invariants

Insertion sort loop invariant:

At the start of each iteration of the for loop of lines 1-8, the subarray A[1 \ldots j - 1] consists of the elements originally in A[1 \ldots j - 1] but in sorted order.

Initialization: Show the loop invariant holds before the first iteration. When \( j == 2 \), the subarray is a single element, the first element of the array. So this subarray is sorted (trivially), which shows the invariant holds.
Insertion Sort Loop Invariants

Insertion sort loop invariant:

At the start of each iteration of the for loop of lines 1-8, the subarray A[1 ... j - 1] consists of the elements originally in A[1 .. j - 1] but in sorted order.

Maintenance: The body of the outer for loop moves A[j-1], A[j-2], A[j-3] and so on by one position to the right until the proper position for A[j] is found (lines 4 - 7). Informally, this keeps the array sorted to the left and right of where A[j] is inserted, preserving the loop invariant. But formally, we should also have a loop invariant for the inner loop.
Insertion Sort Loop Invariants

Insertion sort loop invariant:

At the start of each iteration of the for loop of lines 1-8, the subarray \( A[1 \ldots j - 1] \) consists of the elements originally in \( A[1 \ldots j - 1] \) but in sorted order.

Termination: The loop terminates when \( j \) exceeds the length of \( A \), or when \( j = \text{length} + 1 \). Substituting \( \text{length} + 1 \) for \( j \) in the invariant, we get that the subarray \( A[1 \ldots \text{length}] \) consists of the elements originally in \( A[1 \ldots \text{length}] \) but in sorted order. Since this is the entire array, that proves our algorithm correct.
Analyzing Algorithms
Analyzing an algorithm means predicting the resources that the algorithm will require.

This usually means computational time, but it can also apply to memory, communication bandwidth or other computer hardware usage.
Analyzing Algorithms

We will use a random-access machine (RAM) model of computation in this course. You can read the details in Chapter 2.2.

In short, it is important to note that in this model:
• Operations occur in sequential order (there aren’t concurrent operations).
• Memory hierarchy effects are ignored (for simplicity).
• Each instruction takes a constant amount of time.
Analysis of Insertion Sort

The time taken to sort an array using insertion sort depends on the length of the array. For example, an array of length 3 can be sorted much faster than an array of length 1000.

This is true of most algorithms, so traditionally the runtime of an algorithm is described as a function of the size of its input.
The time taken to sort an array using insertion sort depends on the length of the array. For example, an array of length 3 can be sorted much faster than an array of length 1000.

This is true of most algorithms, so traditionally the runtime of an algorithm is described as a function of the size of it’s input.
Runtime in Analysis

Runtime in analysis of algorithms on a particular input is typically presented as a number of primitive operations or “steps”. It is an abstract count of things done (where doing those things takes equal time).

For the purposes of this course and the text, a single line of pseudocode takes a constant time (assuming it isn’t calling another function). Formally, the $i$th line takes time $c_i$, where $c_i$ is a constant.

In general this is a pretty fair assumption given how our model and most computers operate.
Breaking Down Insertion Sort

INSERTION-SORT(A)
1. for \( j = 2 \) to length[A]                      \hspace{1cm} cost \hspace{1cm} times
2.   do key = A[j]                                \( c_1 \) \hspace{1cm} \( n \)
3.     //insert A[j] into the sorted sequence A[1..j - 1]   \hspace{1cm} 0 \hspace{1cm} \( n-1 \)
4.     i = j - 1                                     \( c_4 \) \hspace{1cm} \( n-1 \)
5.     while i > 0 and A[i] > key                   \( c_5 \) \hspace{1cm} \( \sum_{j=2}^{n} t_j \)
6.         do A[i + 1] = A[i]                       \( c_6 \) \hspace{1cm} \( \sum_{j=2}^{n} (t_j - 1) \)
7.             i = i - 1                             \( c_7 \) \hspace{1cm} \( \sum_{j=2}^{n} (t_j - 1) \)
8.     A[i + 1] = key                               \( c_8 \) \hspace{1cm} \( n-1 \)

Since we know the cost of each line (and how many times it is executed), we know the total runtime, which is the sum of the cost each line multiplied by the number of times it is executed. So the runtime of INSERTION-SORT with an input of length \( n \), or \( T(N) \) is:

\[
T(n) = c_1 n + c_2 (n - 1) + c_4 (n - 1) + c_5 \sum_{j=2}^{n} t_j + c_6 \sum_{j=2}^{n} (t_j - 1) + c_7 \sum_{j=2}^{n} (t_j - 1) + c_8 (n - 1)
\]

Where \( t_j \) is the number of times the inner loop (lines 5-7) is executed for that value of \( j \).
Summations

If we take the following summation:

\[ \sum_{j=2}^{n} (t_j) \]

We can set \( n = 5 \) (or any other value). If \( n = 5 \), then:

\[ \sum_{j=2}^{5} (t_j) = t_2 + t_3 + t_4 + t_5 \]

Then this is the sum of what comes after the summation for \( j = 2, 3, 4, 5 \).
## Best Case for Insertion Sort

**Algorithm**

```plaintext
INSERTION-SORT(A)
1. for j = 2 to length[A]
2.   key = A[j]
3.   //insert A[j] into the sorted sequence A[1..j - 1]
4.   i = j - 1
5.   while i > 0 and A[i] > key
7.         i = i - 1
8.   A[i + 1] = key
```

cost times
---
$c_1$ $n$
$c_2$ $n - 1$
$c_3$ $0$
$c_4$ $n - 1$
$c_5$ $\Sigma_{j=2}^{n} t_j$
$c_6$ $\Sigma_{j=2}^{n} (t_j - 1)$
$c_7$ $\Sigma_{j=2}^{n} (t_j - 1)$
$c_8$ $n - 1$

The best case for insertion sort happens when the array is already sorted. In this case, the statement $A[i] > key$ on line 6 is always false and the loop immediately terminates. This means $t_j = 1$, and then:

$$T(n) = c_1 n + c_2 (n - 1) + c_4 (n - 1) + c_5 \Sigma_{j=2}^{n} (t_j) + c_6 \Sigma_{j=2}^{n} (t_j - 1) + c_7 \Sigma_{j=2}^{n} (t_j - 1) + c_8 (n - 1)$$

From the simplified version of $T(n)$ we can see that it increases in runtime linearly with the size of $n$ (as $c_1 \ldots c_8$ are all constants).
Worst Case for Insertion Sort

```
INSERTION-SORT(A)
1. for j = 2 to length[A]  
2.     do key = A[j]   
3.     //insert A[j] into the sorted sequence A[1..j - 1]  
4.     i = j - 1  
5.     while i > 0 and A[i] > key  
7.         i = i - 1  
8.     A[i + 1] = key
```

The worst case for insertion sort happens when the array is in reverse sorted order. In this case, the statement $A[j] > key$ on line 5 is always true and the loop runs for all values of $i$. This means $t_j = j$. Since:

\[
\sum_{j=2}^{n} j = \frac{n(n+1)}{2} - 1 \\
\sum_{j=2}^{n} (j - 1) = \frac{n(n-1)}{2}
\]

We can fill in our original version of $T(n)$:

\[
T(n) = c_1 n + c_2 (n-1) + c_4 (n-1) + c_5 \left( \frac{n(n+1)}{2} - 1 \right) + c_6 \left( \frac{n(n-1)}{2} \right) + c_7 \left( \frac{n(n-1)}{2} \right) + c_8 (n - 1)
\]

\[
T(n) = \left( \frac{c_5 + c_6 + c_7}{2} \right) n^2 + (c_1 + c_2 + c_4 + \frac{c_5 - c_6 - c_7}{2} + c_8) n - (c_2 + c_4 + c_5 + c_8)
\]
Worst Case for Insertion Sort

The worse case scenario has a runtime which increases quadratically:

\[ T(n) = \left( \frac{c_5 + c_6 + c_7}{2} \right) n^2 + (c_1 + c_2 + c_4 + \frac{c_5 - c_6 - c_7}{2} + c_8)n - (c_2 + c_4 + c_5 + c_8) \]

Because it is similar to the quadratic function (remember \( c_1 \) ... \( c_8 \) are constants, their value doesn’t change when \( n \) changes):

\[ an^2 + bn + c \]

Compare this to the best case scenario:

\[ T(n) = (c_1 + c_2 + c_4 + c_5 + c_8)n - (c_2 + c_4 + c_5 + c_8) \]

Which is linear:

\[ an + b \]

We can see that not only the size of the data, but also the ordering of the data can be extremely important in determining the runtime of an algorithm.
Worst and Average Case Analysis

Typically we worry about the worst case runtime far more than the best case runtime, for a few reasons:

- We don’t know what input we’ll pass to an algorithm before it gets run.
- It gives us an upper bound on the runtime of the algorithm.
- For some algorithms the worst case occurs often.
- The average case is often about as bad as the worst case. For example in insertion sort they both are quadratic functions (just different constants -- in the average case we have to do the inner loop $j/2$ times instead of $j$ times).
Later we will examine average or expected case analysis, which can be useful. However it does have some problems, mainly determining what the average or expected input would be -- and the average or expected input may be different for different applications.
Order of Growth

In the analysis of insertion sort, we said the worst case scenario was a quadratic function, while the best case scenario was linear. This abstracted the costs of the constants $c_i$. (Also note that the sum of a set of constants is just a different constant).

In algorithmic analysis, we typically abstract things one bit farther. We’re really interested in the rate or order of growth, and this is dominated by the leading term of an equation.

For example, for large values of $n$:

$$an^2 + bn + c \approx an^2$$
Order of Growth

For example, for large values of $n$:

$$an^2 + bn + c \approx an^2$$
So for insertion sort, we say it’s worst-case running time is:

\[ O(n^2) \]

“big oh of n-squared” or “oh n-squared”

An algorithm is faster than another algorithm if its worst case running time has a lower order of growth.

Note that for small values of \( n \), the ‘faster’ algorithm may be slower because of constants, but for as \( n \) increases this constants are overcome.

For example, even (if \( n \) is large enough):

\[ 23984729384729837423O(n^2) < O(n^3) \]
Designing Algorithms
We saw with insertion sort that it used an incremental (or iterative) approach to designing the algorithm.

Mergesort uses a different approach, \textit{divide-and-conquer}, which has a much faster worst case scenario than insertion sort.

Divide-and-conquer algorithms often are also easily analyzed with techniques described later in Chapter 4.
Divide-and-Conquer

Has three steps:

- **Divide** the problem into a number of subproblems.
- **Conquer** the subproblems by solving them recursively (divide them again if possible). If the subproblem sizes are small enough, however, just solve the subproblems in a straightforward manner.
- **Combine** the solutions to the subproblems into the solution for the original problem.
Mergesort

Has three steps:

- **Divide** the $n$-element array into two subarrays of $n/2$ elements each.
- **Conquer** the subproblems by sorting them using merge sort (which will continue to subdivide the subarrays until they are length 1).
- **Combine** the two now sorted subsequences to produce the sorted result.
The key to the mergesort algorithm is that it is possible to efficiently sort together two sorted arrays. In fact it is possible to merge the sorted subarrays into a sorted array in $O(n)$ time.
MERGE(A, p, q, r)
1. \( n_1 = q - p + 1 \)
2. \( n_2 = r - q \)
3. create arrays L[1 .. \( n_1+1 \)] and R[1 .. \( n_2+1 \)]
4. for \( i = 1 \) to \( n_1 \)
5. \hspace{1em} do L[i] = A[p + i - 1]
6. for \( j = 1 \) to \( n_2 \)
7. \hspace{1em} do R[i] = A[q + j]
8. L[\( n_1 + 1 \)] = \textit{infinity} // or maximum possible value
9. R[\( n_1 + 1 \)] = \textit{infinity} // or maximum possible value
10. \( i = 1 \)
11. \( j = 1 \)
12. for \( k = p \) to \( r \)
13. \hspace{1em} do if L[i] \(\leq\) R[j]
14. \hspace{1em} then A[k] = L[i]
15. \hspace{1em} i = i + 1
16. \hspace{1em} else A[k] = R[j]
17. \hspace{1em} j = j + 1
MERGE Pseudocode

A is the array.

MERGE(A, p, q, r)
1. \( n_1 = q - p + 1 \)
2. \( n_2 = r - q \)
3. create arrays L[1 .. \( n_1+1 \)] and R[1 .. \( n_2+1 \)]
4. for \( i = 1 \) to \( n_1 \)
   5. \( \text{do } L[i] = A[p + i - 1] \)
6. for \( j = 1 \) to \( n_2 \)
   7. \( \text{do } R[i] = A[q + j] \)
8. \( L[n_1 + 1] = \text{infinity } // \text{or maximum possible value} \)
9. \( R[n_1 + 1] = \text{infinity } // \text{or maximum possible value} \)
10. \( i = 1 \)
11. \( j = 1 \)
12. for \( k = p \) to \( r \)
13.   \( \text{do if } L[i] \leq R[j] \)
14.     then \( A[k] = L[i] \)
15.     \( i = i + 1 \)
16.     else \( A[k] = R[j] \)
17.     \( j = j + 1 \)
MERGE Pseudocode

\[ p \leq q < r \] are indices in the array. These represent the beginning, middle and end of our subarrays.

\[
\text{MERGE}(A, p, q, r) \\
1. \quad n_1 = q - p + 1 \\
2. \quad n_2 = r - q \\
3. \quad \text{create arrays } L[1 .. n_1+1] \text{ and } R[1 .. n_2+1] \\
4. \quad \text{for } i = 1 \text{ to } n_1 \\
5. \quad \quad \text{do } L[i] = A[p + i - 1] \\
6. \quad \text{for } j = 1 \text{ to } n_2 \\
7. \quad \quad \text{do } R[i] = A[q + j] \\
8. \quad L[n_1 + 1] = \text{infinity} // \text{or maximum possible value} \\
9. \quad R[n_1 + 1] = \text{infinity} // \text{or maximum possible value} \\
10. i = 1 \\
11. j = 1 \\
12. \text{for } k = p \text{ to } r \\
13. \quad \text{do if } L[i] \leq R[j] \\
14. \quad \quad \text{then } A[k] = L[i] \\
15. \quad \quad i = i + 1 \\
16. \quad \quad \text{else } A[k] = R[j] \\
17. \quad j = j + 1 \]
Array Indices

MERGE(A, p, q, r)
1. $n_1 = q - p + 1$
2. $n_2 = r - q$

If $p = 1$, $q = 3$, $r = 6$ then:

$$n_1 = 3 - 1 + 1 = 3$$
$$n_2 = 6 - 3 = 3$$
MERGE Pseudocode

MERGE(A, p, q, r)
1. \( n_1 = q - p + 1 \)
2. \( n_2 = r - q \)
3. create arrays L[1 .. \( n_1+1 \)] and R[1 .. \( n_2+1 \)]

\( i = 5, j = 5, k = 16 \)

\( L[i] = \text{inf} \)
\( R[j] = \text{inf} \)

\( k \) is greater than \( r \), so the for loop terminates and we are finished.
MERGE Loop Invariant

At the start of each iteration of the for loop of lines 12-17, the subarray \( A[p..k-1] \) contains the \( k - p \) smallest elements of \( L[1..n_1 + 1] \) and \( R[1..n_2 + 1] \), in sorted order. Moreover, \( L[i] \) and \( R[j] \) are the smallest elements of their arrays that have not been copied back into \( A \).
MERGE Loop Invariant

MERGE(A, p, q, r)
1. \( n_1 = q - p + 1 \)
2. \( n_2 = r - q \)
3. create arrays L[1 .. \( n_1+1 \)] and R[1 .. \( n_2+1 \)]
4. for \( i = 1 \) to \( n_1 \)
5. \quad do L[i] = A[p + i - 1]
6. for \( j = 1 \) to \( n_2 \)
7. \quad do R[i] = A[q + j]
8. L[\( n_1 + 1 \)] = infinity //or maximum possible value
9. R[\( n_2 + 1 \)] = infinity //or maximum possible value
10. i = 1
11. j = 1
12. for k = p to r
13. \quad do if L[i] <= R[j]
14. \quad \quad then A[k] = L[i]
15. \quad \quad i = i + 1
16. \quad else A[k] = R[j]
17. \quad j = j + 1

Important to note that they are the smallest elements because we added infinity into the L and R subarrays.

At the start of each iteration of the for loop of lines 12-17, the subarray A[p .. k-1] contains the \( k - p \) smallest elements of L[1 .. \( n_1 + 1 \)] and R[1 .. \( n_2 + 1 \)], in sorted order. Moreover, L[i] and R[j] are the smallest elements of their arrays that have not been copied back into A.
**Invariant:** At the start of each iteration of the for loop of lines 12-17, the subarray $A[p..k-1]$ contains the $k - p$ smallest elements of $L[1..n_1 + 1]$ and $R[1..n_2 + 1]$, in sorted order. Moreover, $L[i]$ and $R[j]$ are the smallest elements of their arrays that have not been copied back into $A$.

**Initialization:** Before the first loop, $k = p$, so $A[p..k - 1]$ is empty. It contains the $k - p = 0$ smallest elements of $L$ and $R$, and since $i = j = 1$, both $L[i]$ and $R[j]$ are the smallest elements of their arrays that have not been copied back into $A$ ($L$ and $R$ are sorted).
MERGE Loop Invariant

Invariant: At the start of each iteration of the for loop of lines 12-17, the subarray $A[p..k-1]$ contains the $k - p$ smallest elements of $L[1..n_1 + 1]$ and $R[1..n_2 + 1]$, in sorted order. Moreover, $L[i]$ and $R[j]$ are the smallest elements of their arrays that have not been copied back into $A$.

Maintenance: Suppose $L[i] \leq R[j]$. Then $L[i]$ is the smallest element not yet copied back into $A$. Because $A[p..k-1]$ contains the smallest $k - p$ elements, after line 14 copies $L[i]$ into $A[k]$, the subarray $A[p..k]$ will contain the $k - p + 1$ smallest elements. Then incrementing $k$ (in the for loop update) and $i$ (in line 15) reestablishes the loop invariant.

If $L[i] > R[j]$ then lines 16-17 perform a similar action to maintain the invariant.
**MERGE Loop Invariant**

**Invariant:** At the start of each iteration of the for loop of lines 12-17, the subarray A[p..k-1] contains the $k - p$ smallest elements of $L[1..n_1 + 1]$ and $R[1..n_2 + 1]$, in sorted order. Moreover, $L[i]$ and $R[j]$ are the smallest elements of their arrays that have not been copied back into $A$.

**Termination:** At termination, $k = r + 1$. By the loop invariant, the subarray $A[p..k-1]$, which is $A[p..r]$, contains the $k - p = r - p + 1$ smallest elements of $L[1..n_1 + 1]$ and $R[1..n_2 + 1]$, in sorted order. The arrays $L$ and $R$ together contain $n_1 + n_2 + 2 = r - p + 3$ elements. This means all but the two largest elements (the infinities) have been copied back into $A$. 

Merge Runtime

MERGE(A, p, q, r)
1. \( n_1 = q - p + 1 \)
2. \( n_2 = r - q \)
3. create arrays \( L[1 .. n_1+1] \) and \( R[1 .. n_2+1] \)
4. \textbf{for} \( i = 1 \) \textbf{to} \( n_1 \)
   \textbf{do} \( L[i] = A[p + i - 1] \)
5. \textbf{for} \( j = 1 \) \textbf{to} \( n_2 \)
   \textbf{do} \( R[i] = A[q + j] \)
6. \( L[n_1 + 1] = \text{infinity} \) \textit{// or maximum possible value} \n7. \( R[n_2 + 1] = \text{infinity} \) \textit{// or maximum possible value} 
8. \( i = 1 \)
9. \( j = 1 \)
10. \textbf{for} \( k = p \) \textbf{to} \( r \)
11. \textbf{do} if \( L[i] \leq R[j] \)
12. \textbf{then} \( A[k] = L[i] \)
13. \( i = i + 1 \)
15. \( j = j + 1 \)

Lines 1-3 and 8-11 take constant time. The for loops of lines 4-7 each take \( O(n) \) time, and \( O(n_1 + n_2) = O(n) \).

The for loop of lines 12-17 performs another \( n \) iterations, so again \( O(n + n_3) = O(2n) = O(n) \).

Therefore, \texttt{MERGE} takes \( O(n) \) time.
With \textsc{merge} defined we can finally get back to \textsc{mergesort}. We can see that \textsc{merge} does most of the work. All we need to do is get the middle of the array, call \textsc{mergesort} on either side and then \textsc{merge} to combine the two sorted subarrays.

To call \textsc{mergesort} on a whole array $A$, use $p = 1$ and $r = A.\text{length}$:

\begin{verbatim}
MERGESORT(A, 1, A.length)
\end{verbatim}

This is \textit{recursion} -- having a function call itself, and it is a very useful and important programming concept.
A common example of recursion is the Fibonacci sequence, which occurs often in nature.

The image on the left is the head of a chamomile flower, which is arranged with 21 (blue) and 13 (aqua) spirals -- Fibonacci numbers. This is a common occurrence in many plants, like pineapples fruitlets, artichoke flowering, and the arrangement of leaves on a stem.

The Fibonacci sequence is: 0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, ...
Fibonacci Sequence

We can calculate the Fibonacci sequence as follows:

FIBONACCI(i)
1. if (i == 0) return 0
2. if (i == 1) return 1
3. \( t_1 = 0, \ t_2 = 1, \ n = 0 \)
4. for \( j = 2 \) to \( i \)
5. \( n = t_1 + t_2 \)
6. \( t_1 = t_2 \)
7. \( t_2 = n \)
8. return \( n \);
Fibonacci Sequence

We can calculate the Fibonacci sequence as follows:

FIBONACCI(i)
1. if \(i == 0\) return 0
2. if \(i == 1\) return 1
3. \(t_1 = 0, t_2 = 1, n = 0\)
4. for \(j = 2\) to \(i\)
5. \(n = t_1 + t_2\)
6. \(t_1 = t_2\)
7. \(t_2 = n\)
8. return \(n\);

Or using recursion:

FIBONACCI-REC(i)
1. if \(i == 0\) return 0
2. else if \(i == 1\) return 1
3. else return FIBONACCI-REC(i-1) + FIBONACCI-REC(i-2)
Fibonacci Sequence

We can calculate the Fibonacci sequence as follows:

FIBONACCI(i)
1. if (i == 0) return 0
2. if (i == 1) return 1
3. $t_1 = 0$, $t_2 = 1$, $n = 0$
4. for $j = 2$ to $i$
5. $n = t_1 + t_2$
6. $t_1 = t_2$
7. $t_2 = n$
8. return $n$;

Or using recursion:

FIBONACCI-REC(i)
1. if (i == 0) return 0
2. else if (i == 1) return 1
3. else return FIBONACCI-REC(i-1) + FIBONACCI-REC(i-2)

The recursive version is much simpler!
Analyzing Divide-and-Conquer Algorithms
Analyzing D&C Algorithms

When algorithms (or functions) contain a call to themselves, we call this *recursion*.

For recursive algorithms, we usually describe their runtime using a *recurrence* (or *recurrence equation*).
Recurrence Equations

Recurrences are made from the three steps of the divide-and-conquer paradigm:

\[ T(n) \text{ is the running time on a problem of size } n. \]

If the problem size is small enough (in the case of merge sort, \( n = 1 \), or really \( n = 2 \)), \( n \leq c \), then the run time for that \( n, T(n = 1) = O(1) \).

The original problem will be divided into \( a \) subproblems, each \( b \) the size of the original. It takes \( T(n/b) \) time to solve a sub problem, and we need to solve \( a \) of them, so it takes \( aT(n/b) \) to solve all of them.

It takes time \( D(n) \) to divide the problem, and time \( C(n) \) to combine the subproblems.
Recurrence Equations

Putting this together, we get:

\[
T(n) = \begin{cases} 
O(1) & \text{if } n \leq c \\
D(n) + aT(n/b) + C(n) & \text{otherwise}
\end{cases}
\]

(aside) The LaTeX for this is:

\[
T(n) = \begin{cases} 
O(1) & \text{if } n \leq c \\
D(n) + aT(n/b) + C(n) & \text{otherwise}
\end{cases}
\]
Recurrence Equations

Putting this together, we get:

\[ T(n) = \begin{cases} 
O(1) & \text{if } n \leq c \\
D(n) + aT(n/b) + C(n) & \text{otherwise}
\end{cases} \]

Our trivial case (two arrays of length 1 that are already sorted).
Recurrence Equations

Putting this together, we get:

\[ T(n) = \begin{cases} 
  O(1) & \text{if } n \leq c \\
  D(n) + aT(n/b) + C(n) & \text{otherwise}
\end{cases} \]

The time to divide our current problem into subproblems.
Recurrence Equations

Putting this together, we get:

\[ T(n) = \begin{cases} 
O(1) & \text{if } n \leq c \\
D(n) + aT(n/b) + C(n) & \text{otherwise}
\end{cases} \]

The time to calculate the subproblems.
Recurrence Equations

Putting this together, we get:

\[ T(n) = \begin{cases} 
    O(1) & \text{if } n \leq c \\
    D(n) + aT(n/b) + C(n) & \text{otherwise}
\end{cases} \]

The time to combine the subproblems.
Analyzing Mergesort

MERGESORT(A, p, r) //if p == r then the length of the
1. if p < r //subarray is 1 and it is already sorted.
2. q = floor((p + r) / 2)
3. MERGESORT(A, p, q)
4. MERGESORT(A, q + 1, r)
5. MERGE(A, p, q, r)

We have our three steps:

Divide: (lines 1 and 2) This just finds the center of the current part of the array. The time of this is D(n) = O(1), because it takes constant time.

Conquer: (lines 3 and 4) We need to solve two subproblems, each of size \(n/2\). So filling in \(a = 2\) and \(b = 2\), this part takes \(aT(n/b) = 2T(n/2)\) time.

Combine: (line 5) We have already figured out the runtime of the MERGE algorithm, which takes \(O(n)\) time, so \(C(n) = O(n)\).
Analyzing Mergesort

`MERGESORT(A, p, r)`  // if p == r then the length of the
// subarray is 1 and it is already sorted.

1. if p < r
2. \( q = \text{floor}((p + r) / 2) \)
3. \( \text{MERGESORT}(A, p, q) \)
4. \( \text{MERGESORT}(A, q + 1, r) \)
5. \( \text{MERGE}(A, p, q, r) \)

Combining everything from the previous steps, we get:

\[
T(n) = \begin{cases} 
O(1) & \text{if } n \leq c \\
D(n) + aT(n/b) + C(n) & \text{otherwise}
\end{cases}
\]

or, because the \( O(n) \) dominates the \( O(1) \):

\[
T(n) = \begin{cases} 
O(1) & \text{if } n \leq c \\
2T(n/2) + O(n) & \text{otherwise}
\end{cases}
\]
The “Master Theorem”

MERGESORT(A,p,r) //if p == r then the length of the
1. if p < r //subarray is 1 and it is already sorted.
2. q = floor((p + r) / 2)
3. MERGESORT(A,p,q)
4. MERGESORT(A,q + 1,r)
5. MERGE(A,p,q,r)

The “master theorem” shows that:

\[ T(n) = \begin{cases} 
O(1) & \text{if } n \leq c \\
2T(n/b) + O(n) & \text{otherwise}
\end{cases} \]

is equivalent to \( T(n) = O(n \lg n) \).

This is proven in detail in Introduction to Algorithms - Chapter 4 (so we won’t get into that).
Analyzing Mergesort

We can rewrite:

\[
T(n) = \begin{cases} 
O(1) & \text{if } n \leq c \\
2T(n/b) + O(n) & \text{otherwise} 
\end{cases}
\]

As:

\[
T(n) = \begin{cases} 
c & \text{if } n = 1 \\
2T(n/2) + cn & \text{otherwise} 
\end{cases}
\]

Because \(O(1)\) is constant time, and \(O(n)\) ignores constants multiplied by \(n\).
Analyzing Mergesort

The different levels of mergesort all add up to a runtime of $cn$ and there are $\lg n$ levels, so the runtime is $O(n \lg n)$.
Analyzing Mergesort

We can show that there are $n \lg n$ levels, because:

Level 1 has 1 leaf. \hspace{1cm} \lg 1 = 1
Level 2 has 2 leaves. \hspace{1cm} \lg 2 = 2
Level 3 has 4 leaves. \hspace{1cm} \lg 4 = 3
Level 4 has 8 leaves. \hspace{1cm} \lg 8 = 4
Level 5 has 16 leaves. \hspace{1cm} \lg 16 = 5
...
Level n has $n^2$ leaves. \hspace{1cm} \lg n^2 = n
